PERIODIC WIND COMPONENTS AT METEOR HEIGHTS

by
R. G. Roper* and W. G. Elford†

ABSTRACT

21667

The measurement of winds in the height range from 80 to 100 km by means of radio reflections from the ionized trails of meteors is a well established technique. Until recently, however, the full potential of this technique had not been realized. The purpose of this report is to demonstrate the power of an analysis developed by Groves (1959), which has been applied to the data collected at Adelaide (35° S) for the thirteen months from December, 1960 to December, 1961, inclusive. The results show that the most significant periodic zonal and meridional wind components are the 24 hour and 12 hour, with a smaller 8 hour component occasionally present. In general, the vertical component is random, with an amplitude from one to two orders of magnitude less than that of the horizontal wind.

PERIODIC WIND COMPONENTS AT METEOR HEIGHTS

by

R. G. Roper and W. G. Elford

INTRODUCTION

The purpose of this report is two-fold, presenting as it does a summary of upper atmosphere wind measurements carried out at Adelaide (35° S) during 1961, as well as documenting the computer programs used in the computation and analysis of these winds. The measurements were obtained from the radio observation of drifting meteor trails, and have revealed a detailed picture of the diurnal and seasonal motion of the atmosphere throughout the height range from 80 to 100 km.

The Meteor Data

The Adelaide Meteor Project employs a combination of continuous wave and pulse techniques to measure the position and line of sight drift of each meteor trail observed. A description of the method has been given by Robertson, Liddy and Elford (1953).

The parameters measured by the system are

- a. the line of sight drift of the trail.
- b. the direction cosines of the reflection point on the trail relative to NS and EW axes.
- c. the radar range of the echo point, and
- d. the time of occurrence of the echo.

The echo rate is not constant with time; an average of 5 useable wind echoes per hour was obtained during the 1961 survey. To obtain enough data for analysis, records were taken for an average of nine consecutive days about the middle of each month. The mean height of all echoes for each month was 93 (± 1) km, and reliable winds were obtained for the height range 80 to 100 km.

The Analysis

In his meteor wind analysis, Groves (1959) sets up a wind model against which the meteor data is matched. The parameters specifying the model are the coefficients of the polynomial wind variations with height and time. These are conveniently expressed in tabular form.

Zonal	Meridional	Vertical
a_{10}	a_{20}	a_{30}
$a_{11} S$	$a_{21} S$	$a_{31} S$
$a_{12} S^2$	$a_{22} S^2$	$a_{32} S^2$
.	.	.
.	.	.
$a_{1n} S^n$	$a_{2n} S^n$	$a_{3n} S^n$
$b_{10} \sin \omega t$	$b_{20} \sin \omega t$	$b_{30} \sin \omega t$
$c_{10} \cos \omega t$	$c_{20} \cos \omega t$	$c_{30} \cos \omega t$
$b_{11} S \sin \omega t$	$b_{21} S \sin \omega t$	$b_{31} S \sin \omega t$
$c_{11} S \cos \omega t$	$c_{21} S \cos \omega t$	$c_{31} S \cos \omega t$
.	.	.
.	.	.
$b_{1n} S^n \sin \omega t$	$b_{2n} S^n \sin \omega t$	$b_{3n} S^n \sin \omega t$
$c_{1n} S^n \cos \omega t$	$c_{2n} S^n \cos \omega t$	$c_{3n} S^n \cos \omega t$

where S is the normalized height given by

$$S = (2h - z_{\max} - z_{\min}) / (z_{\max} - z_{\min})$$

with z_{\max} , z_{\min} the maximum and minimum heights respectively over which the profile is fitted and h is the height variable within the range z_{\min} , z_{\max} .

If the variations with height in the prevailing wind and the component of period $T = 2\pi/\omega$ are taken as

a polynomial of order 2 in the EW direction

" 3 in the NS direction

and a constant in the vertical (constant with height, not time)

then 24 parameters (a_{ij} , b_{ij} , c_{ij}) are required to specify the motion. These parameters are determined by matching the data to the model, using the method of least squares.

Application of the Groves Analysis to the Meteor Data

No attempt will be made here to present the mathematics of the analysis; the reader is referred to Groves (1959). The IBM 7094 FORTRAN IV program which performs this analysis of the meteor data is listed as program ERG in Appendix I. The number of parameters best specifying the height profiles have been arrived at by trial and error. In this context, the parameters "best" specifying the profiles are the coefficients of the minimum order polynomials which adequately represent the height structure of the mean motion. Calculating the coefficients of the terms of higher order than necessary is extremely wasteful in terms of computer execution time. For example, the calculation for a total of 70 periodic components of the coefficients of a cubic variation with height of the zonal (EW) component, a quartic variation of the meridional (north south), and a constant vertical wind (30 coefficients in all for each periodicity) for 1000 line of sight drifts measured over 9 days takes 42 minutes of execution time on an IBM 7094 Model 2. Assumption of a quadratic zonal, cubic meridional and constant vertical variation (24 coefficients) results in an execution time of 22 minutes, a little over half that of the previous computation. Attempting to over-specify the variations in the wind can also cause the matching process to become unstable, and this has been observed with (3,4,0) profiles. No such instability has been encountered in any of the months so far processed with a (2,3,0) profile.

The Presentation of the Results

The digital output from program ERG (consisting of the amplitude and phase of each periodic component, together with the RMS error in each, for each of 16 heights in the range from 75 to 105 km) is both listed and written on magnetic tape. This tape provides input for the plotter program listed in

Appendix II. The program PLOT writes a low density binary tape suitable for use on the EAI Data Plotter. All the graphs presented in this report are copies of those produced by the EAI machine.

The following are definitions of the quantities presented graphically in the next section.

- a. The wind amplitude spectrum (for a given height). The amplitude of each periodic component is plotted against period for each of the three wind components (zonal, meridional and vertical).
- b. The "specific" energy spectrum (for a given height). The "specific" wind energy is the wind energy per unit mass, calculated for any one period τ as the sum of the squares of the zonal (u), meridional (v), and vertical (w) amplitudes of period τ .

i.e.,

$$E_\tau = u_\tau^2 + v_\tau^2 + w_\tau^2 \text{ (metres/sec)}^2$$

Reduction of Actual Data

An average of 800 echoes for each of the months from December, 1960 to December, 1961, inclusive, have been subjected to the analysis outlined in the previous sections.

The following parameters were used as a basis for the analysis for each month.

1. Only those echoes falling within the height range 75 to 105 km were processed.
2. Both prevailing and periodic zonal components were allowed up to a quadratic variation with height over this height range.
3. Similarly, both prevailing and periodic meridional components were allowed up to a cubic variation.
4. The vertical component was considered to be constant with height, but able to vary with time.
5. Amplitudes and phases of periodic components were calculated for the range of from 0.5 cycles/day to 4 cycles/day (48 hour to 6 hour periods) in increments of 0.05 cycles per day.

The following features have been chosen as being most descriptive of the characteristics of the periodic motion in the height range from 80 to 100 km.

- a. The variation of the wind energy spectrum with height, as measured at 83, 91 and 97 km.
- b. The amplitude spectra for zonal, meridional and vertical components as measured at the mean monthly echo height of 93 km.

The six graphs for each month from December, 1960 to December, 1961 appear as Figures 1a to 14f, inclusive.

DISCUSSION

Insufficient time has as yet been spent on examination of the results to justify any detailed interpretation. However, the spectra presented in Figures 1 to 14 confirm without exception that the dominant periodic components in the winds at these levels are the diurnal (24 hour) and semidiurnal (12 hour) components. At the latitude of Adelaide (35° S), the 24 hour is, in general, of comparable magnitude to the 12 hour, except at the equinoxes, where the 24 hour predominates. There is evidence in some months of a significant 8 hour component which, when it appears, has an amplitude somewhat less than those of the 24 or 12 hour components.

Although the main concern of this report is to investigate the presence of periodic motions, some reference to the prevailing wind components is pertinent. The zonal winds are shown for three heights in Figure 15. The bars about each plotted point represent the RMS deviation. It can be seen that over the height range 80-100 km the zonal wind is predominantly toward the East. The only strong wind reversal occurs at the upper level, where the wind is toward the West during the winter of 1961. No significant reversals occur at the other levels but the wind has its maximum eastwards amplitude in the spring at 91 km and in the summer at 83 km. As a result of the rapid change in the zonal wind with height the seasonal patterns at 83 and 99 km are almost opposite in phase. This behavior is also reflected in the wind gradients which have maximum values of +4 m/sec/km in summer and -4 m/sec/km in winter.

In contrast to the zonal winds, the meridional winds shown in Figure 16 exhibit an annual behavior which is similar at all levels. In general, northward winds occur during summer and southward winds during winter. A similar meridional variation is found for these levels at Jodrell Bank (53° N) and Mawson (68° S). Thus the meridional flow at these levels is consistent with a

horizontal movement of air from the summer to the winter pole. The Adelaide results show that the meridional wind increases with height over the range 80-100 km and that above 90 km the amplitude of the meridional wind is comparable to that of the zonal wind.

It should be remembered, when further interpreting these results, that one year's data is not by itself sufficient to justify a detailed analysis on a seasonal basis. The results presented here, while considerably more detailed, are still complementary to those already published covering the years 1952 to 1958 (Elford, 1959).

FUTURE WORK

The application of the analysis proposed by Groves to the winds measured by the radio meteor method has been shown here to provide a powerful tool in the investigation of periodic atmospheric motions for the height range from 80 to 100 km. The demonstrated domination of this wind regime by solar influence is only one of the many possible products of the analysis. It is hoped that attention can be given some time in the future to the determination of, for example, the magnitude of the lunar influence on winds at this height. For the present, attention is being given to the more detailed interpretation of the results already obtained.
